I. Introduction

Women's voice and agency play an important role in economic development. Empowering women leads to changes in decision making that directly foster development (Duflo 2012). Under the view that development requires the expansion of human capabilities, violence against women is one of the central inhibitors of economic and social development (Panda and Agarwal 2005). The elimination of violence against women is thus not only a major public health issue (Krug et al. 2002; Bott et al. 2012) but also a key objective of the Sustainable Development Goals (SDGs; United Nations 2015).

High-quality data on intimate partner violence (IPV) is crucial to identify the most vulnerable subgroups, monitor the evolution of violence over time, and facilitate the design of effective policies to prevent and reduce IPV. Unlike other SDGs, for which administrative records are the primary source of data,[1] information

[1] For example, the SDGs rely on administrative records for targets and indicators related to, but not limited to, social protection, production, trade and utilization of major food crops and livestock, tuberculosis incidence, education, and domestic financial institutions. For more details about the primary sources for each target and indicator, see *E-Handbook on Sustainable Development Goals Indicators* (https://unstats .un.org/wiki/display/SDGeHandbook/Home). Also, see Calvo, Razafindrakoto, and Roubaud (2019) for a discussion of data collection for governance-related issues in the SDGs.

collected by the services used by violence victims is biased as a result of selection into reporting and lack of trust to report truthfully (United Nations 2014). This is partly explained by limited access to police stations and health care centers, distrust of the authorities at male-dominated institutions, and lower levels of law enforcement in developing countries. Indeed, a study covering 24 developing countries shows that only 7% of victims of violence against women made a report that can be captured by administrative records (Palermo, Bleck, and Peterman 2014).

Most of the data used to track SDGs on women's agency rely on self-reports from victims. The United Nations (UN) guidelines for producing statistics on violence against women identify population-based surveys as "the best source of data" for estimating the prevalence of these acts of violence (United Nations 2014, 2). Over time, these specialized surveys have achieved great progress in the development of instruments and protocols. Yet the private nature of IPV imposes costs to truthful reporting that even the most rigorous safety and privacy protocols for surveys using direct questions could not completely overcome. Women who survive IPV face emotional costs as well as fear of retaliation, loss of economic support, and stigma when reporting their survival status, as the perpetrators tend to be their intimate partners.[2]

Our paper is the first to measure the level of misreporting present in population-based surveys that rely on direct questions on IPV. We conduct a randomized experiment where we compare the prevalence rates of IPV under two different instruments that vary in the degree of privacy they provide to the respondent. While the control group receives a questionnaire that follows the UN best practices, the treatment group answers an alternative instrument that guarantees full anonymity in the report of IPV. The provision of greater privacy when collecting data on IPV could improve the levels of truthful reporting, especially for women with higher costs of exposure.

To maximize the external validity of our study, the questionnaire provided to the control group was based on the Demographic and Health Surveys (DHSs). The DHSs are large, nationally representative surveys applied in over 90 developing countries. Since 2000, the DHSs include a module on IPV that follows the UN recommendations. This module has been applied in over 40 countries and provides the main data source to monitor progress on the IPV indicators of SDG-5 (United Nations 2014). This makes our comparison to the alternative

---

[2] Indeed, the US Bureau of Justice Statistics (Reaves 2017) reports that the most prevalent reasons not to report domestic violence victimization to the police in the United States are personal privacy (32%), protecting the offender (21%), considering that the crime was minor (20%), and fear of retaliation (19%).

instrument widely relevant. The DHS module on IPV is an adaptation of the Conflict Tactics Scale,[3] which asks about specific and objective acts of physical and sexual violence. The Conflict Tactics Scale reduces bias arising from subjective perceptions of violence and provides participants with several opportunities to expose victimization (Ellsberg and Heise 1999; Kishor and Johnson 2004; Bender 2017).

To indirectly record IPV prevalence rates, we rely on list experiments. This methodology increases privacy, as the respondent's status is never revealed, either to the enumerator or to the researchers (Blair and Imai 2012; Glynn 2013). In the standard list experiment, assignment to the treatment is randomized to guarantee that the control group can serve as a counterfactual for the former. The control group is presented with a list of neutral statements and asked to disclose the number of those that are true. Since respondents never reveal which statements are true, privacy levels are greatly increased. In the treatment group, a sensitive statement is added to the list, and once more, respondents report only how many statements are true. The prevalence rate of the sensitive issue is estimated as the difference in the average response to the lists across arms. In our application, we create a list of statements for each of the seven IPV questions in the DHS on physical and sexual violence and ask women in the control group to answer the direct DHS questions and the neutral lists of statements. Women in the treatment arm never receive the direct questions and answer only the extended lists.

We focus on a sample of female microcredit clients from impoverished urban districts in Lima, Peru. This focus is not necessarily a limitation in a region like Latin America and the Caribbean, where 66% of the microcredit client base is female (Convergences 2018). Particularly in Peru, where over five million clients are served by the microfinance sector, our study population becomes extremely relevant.[4] Given this widespread access to microcredit in the country, our sample is able to cover women with diverse backgrounds, diverse socioeconomic statuses, and potentially varying costs of reporting, allowing us to explore important heterogeneous effects of the provision of greater levels of privacy.

Our main result is that, on average, there are no significant differences in reporting across direct and indirect methods on any of the seven acts of physical and sexual violence. This finding is robust to the use of multiple-hypothesis testing and joint tests of statistical significance. Since we closely followed the UN guidelines, this result validates the adequacy of the best available practices when

---

[3] Originally developed by Straus (1979) and later modified and expanded by the World Health Organization (WHO 1997).

[4] For the past 10 years, Peru has been at the top of the ranking of the Global Microscope, an annual report on the "environment for financial inclusion" created by the *Economist* Intelligence Unit. See http://www.eiu.com/landing/Global-Microscope for details.

using direct survey methods to collect data on IPV. In fact, our survey is close to a "stand-alone" survey on violence, because it did not include all the other modules observed in a typical DHS (e.g., maternal and child health, birth history). This focus provides an additional strength to the design, since our power calculations were specifically tailored to the IPV questions, as opposed to other variables, as in the DHS. This allowed us to obtain a large enough sample to accurately measure even the low-prevalence violent events included in the Conflict Tactics Scale.[5]

We also test for differences in reporting across 16 subgroups. In all but one case, IPV reports using direct questions perform as well as those with indirect methods. Thus, for the vast majority of subgroups studied, the use of the UN's best practices to elicit IPV prevalence is supported. It is worth noting that, even after controlling for multiple-hypotheses testing, we find that women with completed tertiary education report higher rates of violence under the list experiments than under the direct methods, while there is no significant difference among the least educated women. This evidence could be consistent with a negative correlation between years of education and traditional views of gender roles (e.g., Angelucci 2008; Marcus and Harper 2015). While this finding cannot be extrapolated, it highlights that even when the best practices to collect IPV data are implemented, differential misreporting patterns could still emerge in certain contexts and subpopulations.

Our study contributes to the scarce body of work measuring misreporting in the case of IPV. It significantly improves upon recent work by Joseph et al. (2017) and Peterman et al. (2017) on IPV using list experiments in developing countries. As explained in more detail below (see sec. II), both studies ignore UN recommendations and use a general statement about violence as the sensitive statement in the list experiments. Moreover, neither study includes a direct question equivalent to the sensitive item in the control questionnaire. Instead, we follow the best recommended practices and compare our indirect method to the DHS direct questions to understand misreporting patterns.

Furthermore, our large sample size overcomes a common problem found in the applications of list experiments in other contexts (e.g., Karlan and Zinman 2012; De Cao and Lutz 2018), where the same subjects are exposed to both direct and indirect questioning. This strategy, the double list experiment, eliminates the anonymity that our experiment is able to provide by assigning subjects in the sample to either a treatment or a control group.

---

[5] As discussed in sec. III.B, we implemented all the recommended protocols in the control and treatment groups. For example, female enumerators were trained specifically to deal with IPV-related issues, we had an emergency questionnaire to be used when interrupted during the IPV section, and support information for victims and surveyors was provided when required.

This study is also related to previous work using list experiments to measure prevalence rates of risky or socially sensitive attitudes or behaviors. Recent applications of list experiments include, for example, Karlan and Zinman (2012), to measure loan proceeds from microfinance loans; Jamison, Karlan, and Raffler (2013), to collect information on sexual behavior; McKenzie and Siegel (2013), to elicit illegal migration rates; Coffman, Coffman, and Ericson (2013), to measure the size of the LGBT population and antigay sentiment; Imai, Park, and Greene (2014), to examine vote selling; and Rosenfeld, Imai, and Shapiro (2016), to study antiabortion support. We argue that the particular nature of IPV imposes costs of self-exposing as a victim that may be quite different from those faced by a criminal or drug abuser.

Finally, our results have ample applications on the topic of measurement error for other SDG indicators. Our approach is especially useful where administrative records are not a reliable data source to measure sensitive behavior, as observed in other settings (Butler et al. 1987; Bound, Brown, and Mathiowetz 2001).

The remainder of the paper is structured as follows. Section II presents some background information on misreporting IPV in survey questions, while section III provides details on the design of our study and the instruments used to implement direct and indirect questions on IPV. Section IV presents and discusses the results, and section V concludes.

II. Misreporting IPV in Surveys

Our paper tests for possible underreporting biases in the measurement of IPV as collected by population-based surveys. These surveys have been identified as the best source of data to monitor progress of the SDG related to women's empowerment (United Nations 2014).

We argue that two features of IPV generate large potential for error in the measurement of prevalence rates even in well-designed specialized surveys. First, this violence is perpetrated by a person known to the victim: her current or ex-partner. Second, it tends to be invisible, as much of it happens behind closed doors and in the privacy of the home.

The nature of IPV may thus lead to measurement biases, as it introduces very large costs to self-identify as an IPV victim. For instance, there is an emotional cost due to her attachment to the offender and the potential sanctions (social or legal) that he may face. If her status as a victim is revealed, a woman may also face the potential loss of her partner's economic support and the risk of retaliation through an escalation of violence against her or her children. Women may also fear stigmatization, from either intrinsic or extrinsic sources (Overstreet and Quinn 2013). However, the costs of being exposed are likely to be heterogeneous. This implies that privacy concerns may differentially prevent women

from truthfully reporting their previous experience of violence, making misreporting more prevalent for specific subgroups.

Despite increasing levels of support for victims to speak up (Klugman et al. 2014), it is still difficult to disclose these violent events and expose the aggressors. As much as security and privacy protocols can be improved upon and emphasized in the fieldwork, direct methods still demand that a woman identify herself as an IPV victim to a surveyor, potentially exposing her and her aggressor. A few nonexperimental studies suggest that higher privacy may lead to more reporting. For example, Ellsberg et al. (2001) compared the prevalences of IPV in Nicaragua from two surveys conducted in different years and found that when safety and privacy protocols are enforced more strictly, higher prevalence rates of IPV are reported. Additionally, the WHO multicountry study asked about past abuse (sexual abuse as a child) twice, so as to compare responses under UN guidelines to those obtained by secretly marking a happy or sad face in a sheet that was not observed by the surveyors. The latter method reported a higher incidence of abuse (García-Moreno et al. 2005).

A few studies have tried to reduce exposure costs by relying on indirect methods that provide full anonymity to respondents and foster truthful reporting. Among these methods, list experiments are the most frequently used.[6] Three recent examples closely related to our paper are Joseph et al. (2017), Peterman et al. (2017), and Bulte and Lensink (2019). Even though their contribution is valuable, they face several limitations. First, Joseph et al. (2017) measures prevalence rates at the household level, asking anyone who opens the door about the violence experienced by all women in the household. Thus, it may be the case that the respondent does not know about the IPV experience of each women in the household or that he himself is the perpetrator. Second, the sensitive statement in the lists is quite general, and it is based on the single-question generic approach ("Has at least one woman member of your household faced physical

---

[6] Alternative methods include qualitative approaches, as in Blattman et al. (2016). The authors combine surveying with ethnographic techniques to uncover misreporting. The method requires that the surveyor team stay for longer periods of time in the field, increasing the costs of data collection. Moreover, since it does not provide additional anonymity to the respondents, the success of the method depends heavily on the surveyors' ability to make the respondent feel safe and comfortable to truthfully report her answers or behavior. Surveyor training then becomes crucial, adding to the cost of the fieldwork and limiting the scaling up of the technique. Kataoka et al. (2010) relies on a small sample ($N = 382$) of pregnant women in Tokyo who were interviewed multiple times at a prenatal clinic. The authors compare face-to-face interviews against a self-administered questionnaire that provides more privacy either dealing with potential external stigma costs of reporting IPV to the nurse or hiding her response from her partner. Other indirect questioning techniques, such as endorsement experiments or randomized-response techniques, are often used in the political science literature, and recent papers have adapted them to measure health outcomes such as abortions (Lara et al. 2006).

aggression from her husband anytime during her life?"), greatly departing from the well-established multiple-question UN guidelines for the measurement of violence. The same holds for Peterman et al. (2017), who target women as respondents but use a general sensitive statement to measure physical violence ("In the last 12 months, have you ever been slapped, punched, kicked, or physically harmed by your partner?"). Bulte and Lensink (2019) also rely on a unique question on IPV, which even varies across methods ("I am regularly hit by my spouse" in the list experiment and "How often did your husband push, slap, beat, or hit you during the last 6 months?" in the direct question). Moreover, the authors include in the same questionnaire the list-experiment questions (either the control or the treatment format), followed by the direct IPV question. This repetition of IPV questions under the two methods for the treatment group could potentially bias the responses to the direct question. In sum, none of these studies is able to measure misreporting relative to the best available IPV direct reporting method, and they do not include a direct question equivalent to the sensitive item in the control questionnaire while adhering to the WHO best practices and protocols.

Our design overcomes all these limitations by (1) focusing on women as respondents, (2) following the UN guidelines for direct questions as well as their privacy and safety protocols throughout the application of the questionnaire, (3) asking the direct questions only to the control group, and (4) comparing the prevalence rates obtained from the indirect method to the ones that come from the DHS direct method.[7] Indeed, we are the first in the field of IPV to experimentally measure the bias in survey-based data.

An additional advantage of our paper is that we are able to analyze the level of misreporting across subgroups defined by individual characteristics. This is particularly relevant, given the evidence in reporting biases documented in other sensitive variables and behaviors. For instance, Gottschalk and Huynh (2010) show that there is substantial measurement error in earnings and that this error is correlated with (true) earnings and positively correlated across time. Dillon et al. (2019) show that self-reported measurement bias in land size leads to overreporting for small plots and underreporting for large plots. In the health literature, Butler et al. (1987) show evidence of nonclassical error in the measurement of arthritis, while Johnston, Propper, and Shields (2009) find a similar pattern in hypertension self-reporting. O'Neill (2012) identifies a negative correlation

---

[7] Recently, De Cao and Lutz (2018) used a list experiment to measure the reporting bias relative to direct questions about attitudes toward female genital cutting in the Afar province of Ethiopia. However, they share some of the limitations mentioned above for the studies on IPV, such as the loss of full anonymity that comes from asking the direct questions to both the treatment and control groups.

between self-reported and anthropometric measures of body mass index. More recently, Bharadwaj, Pai, and Suziedelyte (2015) rely on administrative records and find that underreporting in mental health medication is correlated with age, gender, and ethnicity.[8]

Heterogeneous differences in misreporting may distort targeting strategies and estimated treatment effects of programs intended to reduce IPV prevalence. Many studies have tried to identify the main drivers of this type of violence (e.g., Angelucci 2008; Bobonis, González-Brenes, and Castro 2013; Haushofer and Shapiro 2013; Hidrobo and Fernald 2013; Hidrobo, Peterman, and Heise 2016; Erten and Keskin 2018). When an outcome variable, such as IPV, suffers from classical measurement error, the precision of the treatment effects estimates (i.e., the standard errors) is affected. However, when the error is not classical but rather correlated with a risk factor (e.g., misreporting varies by income and education attainment), then it is impossible to obtain unbiased causal estimates of the variable of interest (see app. B; apps. A and B are available online). Indeed, Gillen, Snowberg, and Yariv (2019) replicate three classic and influential studies on behavioral economics in the United States (but unrelated to IPV) and find that measurement error in control and causal variables explains 30%–40% of variance in choices. Accounting for nonclassical measurement error substantially affects the findings of the studies, showing that the bias introduced is not negligible. Thus, a key goal of our study is to investigate whether there is misreporting across different subgroups in our sample.

III. The Experiment

A. Experimental Design

Our study relies on a survey experiment to measure the impact of an increase in privacy on IPV reporting. Greater privacy is created by reducing respondents' expectations that her report will be shared with others. The treatment varies the survey module on physical and sexual IPV, which allows us to compare prevalence rates across direct and indirect methods. While the control group reveals exposure to physical and sexual IPV through direct DHS questions, the treatment group does so only indirectly, through list experiments.

List experiments are often used to gather opinions and record behaviors related to sensitive issues that are prone to underreporting. The basic design of a list experiment features a control group, which is given a list of S neutral statements, and a treatment group, which receives $S + 1$ statements including the same list

---

[8] A recent article also shows that self-reports on bargaining power coming from men and women within the same household systematically differ; indeed, disagreement varies across assets and activities (Ambler et al. 2019).

received by the control group and an added statement referring to a sensitive issue. Both groups are asked to report the number of statements that hold true, without indicating which ones are in fact true. Random assignment of the treatment implies that the average number of neutral statements that hold true is equal across groups. Thus, the control group serves as a counterfactual for the treatment group, and the prevalence rate of the sensitive statement can be estimated by the difference in the average number of true statements reported across groups.[9]

This paper applies this methodology to measure the bias in prevalence rates of physical and sexual IPV under direct reporting. To mimic the DHS questionnaire, we ask whether the respondent ever experienced IPV as perpetrated by her last partner in both the direct questions and the randomized lists. The structure of the questionnaires for the treatment and control groups is shown in table 1. Both surveys started with general questions on demographics and a memory test (modules 2 and 3). To ease transition into more sensitive questions on physical and sexual IPV, all respondents were given direct questions on emotional violence in module 4. In the physical and sexual violence module, the questionnaires differed, depending on the treatment assignment. In the control group, we administered direct questions on physical and sexual IPV (module 5A) followed by a module with the lists of neutral statements (5B). The treatment group skipped the direct questions and was provided with only the list-experiment questions with the added sensitive statement.

Our study focuses on female microentrepreneurs in impoverished periurban areas in a middle-income country. The experimental sample is drawn from a village banking program run by the Adventist Development and Relief Agency (ADRA) in Lima, Peru's capital. We impose several constraints on the total pool of 1,873 clients (112 banks) in Lima. First, we focus on borrowers aged between

---

[9] Note that full anonymity precludes gathering individual-level data on prevalence for each violent act.

TABLE 2
PREVALENCE RATES OF IPV UNDER DHS-TYPE QUESTIONS

	Observations	Prevalence Rate
Emotional IPV	992	.65
Humiliate	990	.38
Insult	989	.35
Called lazy	990	.27
Threatens to harm	990	.15
Threatens to leave	990	.33
Physical and sexual IPV	518	.46
Pull hair	518	.31
Slap	517	.27
Punch	517	.22
Kick	516	.14
Strangle	518	.05
Knife	518	.05
Unapproved sex practices	516	.09
Any IPV	518	.72

Note. Direct questions about emotional violence were asked to both treatment and control groups. Direct questions about physical and sexual violence applied only to the control group.

18 and 60. Second, we reserve six banks at random for piloting purposes. Finally, we target all clients in banks with monthly meetings scheduled during July 2015. Our final sample includes 1,119 women in 98 banks who were interviewed between July 1 and August 25, 2015.

Women participating in ADRA's microcredit programs are different from the average woman in Lima. As shown in table A.1 (tables A.1–A.4 are available online), ADRA's clients are older, more likely to be married, less educated, and poorer than the women interviewed in Lima in the 2015 Peruvian DHS.[10] ADRA's clients also experience higher levels of physical and sexual violence. Our study does not try to characterize women in Lima but rather focuses on a subgroup of women who tend to be self-employed and who have been the focus of attention of several development interventions, such as microcredit programs.

Data collected using DHS-type direct questions reveals very high prevalence rates of ever experiencing violent acts inflicted by the woman's last partner. As shown in table 2, about 72% of the women in the control group have experienced some type of violence, either emotional, physical, or sexual. The prevalence rate of physical and/or sexual violence is also high, at 46%.

Randomization of the treatment was conducted in the field, at the individual level, right after the surveyor obtained the informed consent of the respondent. Table 3 confirms that the randomization was successful. After cleaning

[10] The DHS restricts its sample to women aged 15–49, as it focuses on fertility. Microcredit programs, including ADRA's, do not follow such an age restriction, and neither does our sample.

the data, we are left with a sample of 992 valid surveys. According to our power calculations, this sample was large enough to detect an effect as small as 3 percentage points.[11]

B. Instruments: Development and Application

Collecting data on violence is quite challenging and demands strict ethical and safety protocols and well-designed instruments. The direct questions on physical and sexual IPV were obtained from the Peruvian DHS. The DHS follows a multiple-question approach that provides participants with several opportunities to respond about physical and sexual violence (Kishor and Johnson 2004). This question format focuses on specific and objective acts of violence, and it is less likely to be affected by different perceptions about what constitutes violence (see Ellsberg and Heise 1999 and Bender 2017 for an extensive discussion).

The list-experiment module includes one list of statements for each victimization act covered in the direct questions. While the control group receives lists that consist of four neutral statements, each list provided to the treatment group ends with an added sensitive statement that corresponds to a given act of violence. We consider seven physical or sexual violence acts inflicted by their actual or past partners: having her hair pulled; being slapped or having her arm twisted; being punched or struck with something that may have hurt her; being kicked or dragged; being strangled or burned; being threatened with a knife, gun, or other weapon; and being forced to perform sex acts she does not approve of.

To guarantee respondents' safety and well-being, we implement all the protocols recommended by the UN when collecting data on IPV, including the application of the survey in a private space and the use of an emergency questionnaire whenever someone interrupts the interview during the violence module. Moreover, to ensure that the protocols were adequately implemented, we give special attention to the selection and training of the surveyors. We selected a team of female surveyors with previous experience on gender issues and gender-based violence. All candidates attended a 3-day training workshop, and only the top performers in the practice sessions were recruited. The workshop itself included a sensitization session provided by a local civil rights organization, Centro de la Mujer Peruana Flora Tristán, which works on gender issues and women's empowerment. All surveyors were trained in the application of both treatment and

---

[11] The baseline violence prevalence rates in the area studied were obtained from the 2015 Peruvian DHS survey. We focused on one of the least frequently reported acts of violence: being forced to perform sex acts she does not approve of. Initial prevalence rate is set at 0.027, with a standard deviation of 0.161. As discussed in our preanalysis plan, our sample size follows a randomization conducted at the individual level, with a minimum detectable effect of 0.03, a significance level of 10%, and power of 0.8.

** Significant at the 5% level.

control questionnaires, which differed only in the way in which we asked about IPV, either direct or indirect elicitation. The questionnaire application, irrespective of the result of the randomization, was undertaken under the same guidelines and protocols recommended by the UN when asking about IPV. Since respondents may be less familiar with indirect questioning techniques such as the list experiments, we expanded the protocols to include the use of visual aids in module 5B. Surveyors were instructed to provide each respondent with a printed copy of the list-experiment questions that corresponded to her randomization outcome. This allowed respondents to follow the list of statements read to them and helped them remember the number of positive answers as they went along the list.

For the list experiments to effectively protect respondents' privacy while providing a good estimator of the prevalence rate, the selection and grouping of neutral statements is crucial. The design of each list has to take into account the trade-off between protecting the respondent and reducing the variability of the responses. On one hand, we want to avoid ceiling effects or floor effects: if a large share of the population is likely to respond that all or none of the neutral statements are true, the respondent is no longer protected. On the other hand, a list that avoids ceiling and floor effects will tend to introduce greater variability in the responses, which could increase the variance of the estimator. Glynn (2013) provides some guidance for the development of lists and shows that introducing negative correlation between the responses to the neutral items in the list limits the variability of the responses while minimizing the likelihood of ceiling or floor effects.

To develop the questionnaires, we piloted 41 neutral statements with a sample of 31 individuals and measured the prevalence rates of each statement. These prevalence rates allowed us to measure the adequacy of the statements in our setting and helped us decide how to group them, depending on their correlation patterns. On the basis of correlation of responses across pairs of statements in

the pilot data, we developed an algorithm that induced negative correlation within the list of nonsensitive statements. First, we chose a grouping that minimized correlation between pairs of statements. Second, we grouped pairs of statements according to optimal negative correlations and checked that the correlation in the full list was still negative. Table A.2 shows the prevalence rates of the 26 statements we kept for the list experiments after removing those with very low prevalence rates. Two statements used in the final instrument were not tested in the pilot. Table A.3 reports the correlation of prevalence rates in each set of statements grouped together. For each of the seven lists, we applied the test proposed by Blair and Imai (2012) where the null hypothesis is "no design effect." In all cases, we fail to reject the null at the 5% confidence level.[12]

One may argue that the inclusion of the direct questions on physical and sexual IPV in the control group could bias the responses in the rest of the survey, including answers to the lists of neutral statements. If that were the case, then answers to all other nonsensitive questions in module 6 would have been affected. Table 4 tests for differences in the answers and nonresponse rates to the last module on client's satisfaction with ADRA, which was applied to control and treatment groups. In only one case did the answers across groups differ, but the magnitude is quite small, and significance holds at only the 10% level (see panel A). Item nonresponse rates are also similar across arms (see panel B). This evidence rules out the possibility that the treatment assignment biased the report of the prevalence rates of neutral statements.

C. Estimation

Let T_i denote the binary treatment assignment to the list experiment, and let L_i be the number of statements that hold true for individual i. The difference-in-means estimator ρ approximates the prevalence rate of the sensitive statement,

$$L_i = \alpha + \rho T_i + \xi_i, \tag{1}$$

---

[12] An alternative approach to test for the internal validity of list experiments has been proposed by Chuang et al. (2019). They compare the responses when the list with S statements includes only neutral statements against a list with statements that are less neutral. The latter list is intended to make the sensitive issue (sexual behavior in their study) less salient and see how this affects the report. The authors found a higher prevalence rate when the sensitive statement was accompanied by other sensitive statements. While they do not compare these two arms against a direct question as in our case, their findings suggest that our experiment, carried out with true neutral lists, may represent a lower bound. Also, it is not clear whether additional biases, if any, are created by the lists that include other sensitive statements. In any case, we argue that the emotional violence module in our questionnaire served as a smooth transition into the physical and sexual IPV questions, reducing the saliency of the sensitive statements in module 5B for the treatment group.

TABLE 4

Note. Differences between control and treatment groups are obtained from regressing each variable on the treatment dummy. Standard errors are in parentheses. VB = village bank.
* Significant at the 10% level.

where additional controls can also be added to the regression model. Let the prevalence rates under the direct questions be denoted p. The level of misreporting between the list experiment and the direct questions is measured by $\rho - p$. Since the control and treatment groups are, on average, equivalent in terms of their true prevalence rates, $\rho - p > 0$ signals the existence of underreporting when DHS-type questions are implemented.

The model estimated with list-experiment data can be further extended to capture prevalence rates for different subsamples, as defined by x_i,

$$L_i = \alpha + \rho' T_i + \gamma x_i + \zeta(T_i \cdot x_i) + \xi_i, \qquad (2)$$

where x_i is a binary variable indicating that individual i has characteristic x. Additional controls besides x_i can potentially be added to the regression model

in equation (2). The term $\rho' + \zeta$ captures the prevalence rate as measured by experimental methods among individuals with $x_i = 1$, while ρ' will measure the prevalence rate for those with $x_i = 0$.[13] These prevalence rates can be compared to their counterpart measures obtained through direct reporting, conditional on x_i.

Since the data produced by list experiments preclude us from obtaining individual-level prevalence rates, we cannot deal with the issue of multiple outcomes by creating aggregate IPV indexes. Thus, we correct for the potential issue of simultaneous inference within each subgroup as defined by x_i, using multiple-hypothesis testing. We rely on the false-discovery rate (FDR)–adjusted q-values as introduced by Benjamini and Hochberg (1995). We implement this correction for the family of seven IPV outcomes for the overall analysis and for each subgroup used in the heterogeneity analysis. The FDR estimates the expected proportion of tests that are false positives among all significant tests. For example, an FDR-adjusted q-value of 0.1 indicates that 10% of the significant tests are false positives. In comparison, an unadjusted p-value of 0.1 implies that 10% of all tests (significant or not) are false positives. Finally, all regressions include controls for the three variables that are not balanced between treatment and control samples: education level, memory test score at the beginning of the survey, and household head status (see table 3). Additionally, we follow Bruhn and McKenzie (2009) and control for additional variables that may have a strong link with the outcome of interest, such as marital status and working status.

IV. Results

Table 5 presents the main findings of our paper. The first and second columns show the prevalence rates using indirect (ρ) and direct (p) reporting methods for physical and sexual IPV. The last column measures the gap, $\rho - p$, for each act of IPV, while the last two rows report the results from a joint test of significance of these gaps for all acts of violence analyzed. On average, IPV rates obtained with direct questions do not differ when compared to experimental methods that provide more privacy to the respondent. For six out of the seven acts of physical violence, the prevalence rates obtained through randomized lists do not significantly differ from those measured using direct DHS-type questions. In fact, after correction for multiple-hypotheses testing using the FDR q-values, none of the seven IPV acts differ across reporting methods. This result is further

---

[13] These are the multivariate regression estimators obtained under linearity in x_i and $T_i \cdot x_i$, as proposed by Blair and Imai (2012).

Estimates of p are obtained from a regression of the direct answer on a constant. Robust standard errors are in parentheses.
* Significant at the 10% level (unadjusted p-values).

reinforced with the joint test, which fails to reject the null hypothesis that the seven gaps are jointly 0. This allows us to rule out an overall reporting bias.[14]

This result validates the quality of IPV data collected under UN guidelines and supports the reliability of population-based surveys. However, it does not rule out misreporting among different groups. More vulnerable groups with higher costs of being exposed could be less likely to truthfully report violence under direct methods that provide limited privacy in the field.

Estimates of the prevalence rates and gaps by different individual characteristics are obtained from estimating equation (2).[15] In particular, we focus on eight characteristics that may be correlated with respondents' costs of being exposed as a victim. These include age, marital status, education level, mother tongue (as a proxy for ethnicity), memory test scores, household head status,

[14] In the control group, the nonresponse rate for the IPV module with the direct questions is 5.4%. List experiments do not lead to a big difference in that respect: the nonresponse rate for the module with list experiments is 3.9% in the treatment group and close to null in the control group.

[15] Table A.4 shows power calculations and the negative predicted value for 10 subgroups, using data from the DHS. Both estimates indicate that we have enough power for at least seven of these subgroups. Potential misreporting in the DHS itself further reduces the possibility that our study is underpowered. Since measurement error in IPV is most likely to emerge as a result of underreporting, power calculations using DHS "biased" baseline values would impose more demanding requirements on the sample size needed to identify an effect.

employment status, and tenure at ADRA. For each of the 16 subsamples (two groups for each of the eight characteristics), table 6 reports the joint significance tests that prevalence rates in all measured acts of physical and sexual IPV are jointly 0. The key finding here is that for all but one of the 16 subsamples, we fail to find IPV reporting differences between direct and indirect methods. This is further confirmed in figures A.2–A.8 (figs. A.1–A.8 are available online), which depict the gaps in prevalence rates for each violent act and subsample. Overwhelmingly, the evidence indicates that the best practices to elicit IPV prevalence rates do not lead to systematic misreporting patterns.

We find differential reporting across DHS-type and list-experiment methods only among women with tertiary education. Table 7 shows that there are large positive gaps in the prevalence rates reported under indirect and direct methods in the group of women with complete tertiary education and that these differences survive the multiple-hypotheses testing correction and the joint test. Less educated women do not exhibit any significant differences by reporting method. The effect among educated women is not capturing a better understanding of the list-experiment questions, since there are no significant

TABLE 6
JOINT SIGNIFICANCE TEST OF $(\rho - p)$: HETEROGENEOUS EFFECTS

Characteristics	χ^2	Prob $> \chi^2$

*** Significant at the 1% level (unadjusted p-values).

differences by characteristics that may proxy better performance in this module (see fig. A.4 for differences by mother's tongue and fig. A.5 for those based on a memory test implemented within the survey). Also, the IPV rates under full anonymity are large enough to reverse the education gradient in violence. Figure 1*a* shows that direct reporting produces a negative correlation between education level and prevalence rates: less educated women report more violence than those with more years of schooling. However, the provision of greater privacy under the list experiment reverses the direction of this relationship, as shown in figure 1*b*. Once the costs of being exposed as a victim are minimized through greater provision of privacy, women with complete tertiary education exhibit higher prevalence rates of physical and sexual IPV, irrespective of the violent act considered.[16]

[16] Putting forward a full explanation for why schooling leads to systematic misreporting in our sample goes beyond the scope of this paper. Nevertheless, we speculate that the source of nonrandom measurement error among more educated women is a higher stigma cost due to more equal views on gender roles. Education provides access to new knowledge, ideas, and lifestyles that expose individuals to gender roles different from the ones accepted in their communities or localities (Marcus and Harper 2015). Since contact with more gender-equal social norms increases the costs imposed by stigma, we rationalize the greater propensity to misreport among the most educated in our sample

The switch in the sign of the correlation between years of education and IPV when moving from direct to indirect methods is also present in very recent evidence from Africa.[17] This reversal, present across different contexts, suggests that the protective effect of education identified by previous studies (Ackerson et al. 2008; Eswaran and Malhotra 2011; Yuan and Hesketh 2019) may be in part driven by misreporting issues when using direct methods. Instead, our result on the positive relationship between education and IPV, under indirect methods, provides supportive evidence for instrumental theories of violence, as discussed in Angelucci (2008), Erten and Keskin (2018), and Tankard, Paluck, and Prentice (2019).

The difference in reporting among highly educated women cannot necessarily be extended to the female population in Lima or to other contexts. As discussed above, female clients of microcredit organizations are not a random sample but rather represent a particular subgroup with lower socioeconomic status and potentially higher levels of empowerment.[18] Nevertheless, the results by education level portrayed here are still useful to highlight the possibility of nonrandom measurement error, potentially context specific, when measuring IPV.

V. Conclusion

This is the first study to measure and characterize the possible bias in direct reporting of violence against women in an experimental setting. We compare lifetime prevalence rates obtained from the most common source of IPV data in developing countries, the violence module of the DHS, to estimates using

---

through this channel. See Lindbeck, Nyberg, and Weibull (1999) for an example of how social norms and stigma are related in the case of welfare recipients.

[17] Cullen (2020) compares direct and indirect methods in Nigeria and Rwanda and finds that the IPV-education relation also depends on how IPV is measured.

[18] Clearly, microcredit access not only may mimic an income transfer but also could have empowerment effects that can play a role in the prevalence of IPV. Indeed, we acknowledge that our sample of women participating in ADRA's microcredit programs is different from the average woman in Lima (see table A.1). Although we are not aware of studies that directly look at the compound effect of microcredit on IPV prevalence, several studies provide evidence on the relationship between a woman's income and IPV. For instance, IPV may decrease as a woman's income goes up, improving the value of her outside option and/or raising her participation constraint in the partnership (Tauchen, Witte, and Long 1991; Farmer and Tiefenthaler 1997; Eswaran and Malhotra 2011; Bobonis, González-Brenes, and Castro 2013; Haushofer and Shapiro 2013). However, other papers show that this effect may be reversed whenever the man feels threatened by the woman's increase in bargaining power or if he decides to use violence as a means to extract resources from her (Angelucci 2008; Tankard, Paluck, and Prentice 2019). In either case, while we recognize that access to microcredit can affect the level of IPV prevalence in our sample, it certainly does not play a role in our findings, since women in both the treatment and control groups in our experiment are members of microcredit programs.
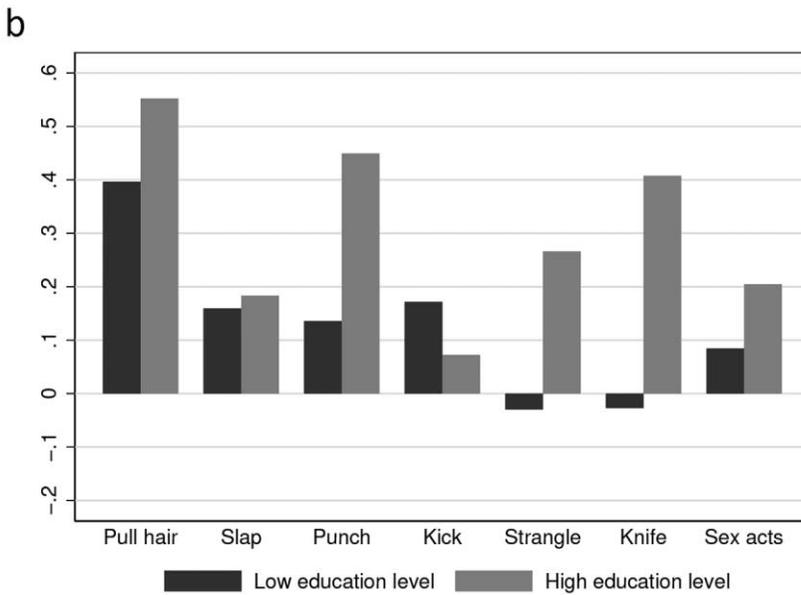

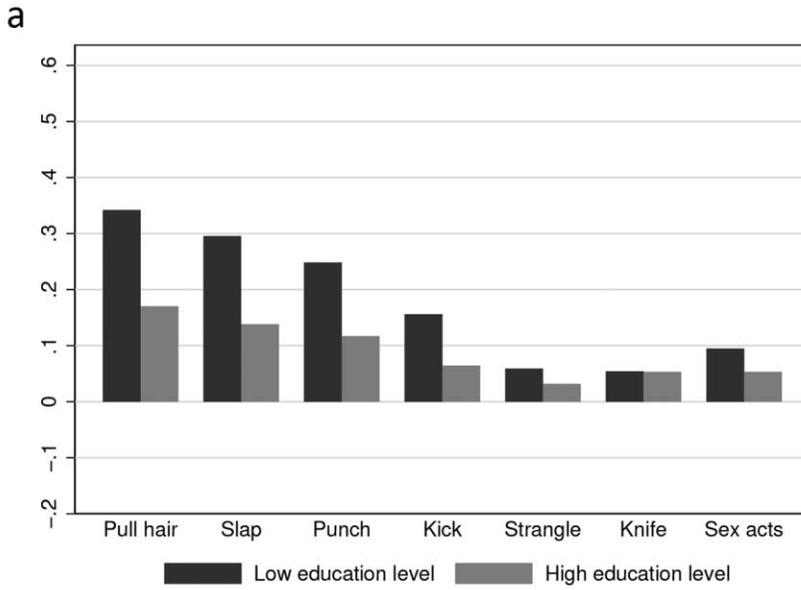

Figure 1. Physical violence prevalence rates by reporting method (*a*, direct reporting; *b*, list experiment) and education level. High education level is defined as completed tertiary education.

indirect questioning techniques that provide full anonymity and minimize exposure costs.

The results show that direct questions are a good source of data to measure prevalence of physical and sexual IPV. It is important to note that our questionnaire is closer to a "stand-alone" survey on violence because we did not include all the other modules embedded in a typical DHS (e.g., maternal and child health, birth history). Overall, our study gives evidence-based support for the UN recommendation of using stand-alone surveys, relative to multiple-objective surveys such as the DHS.

Furthermore, we also reject the existence of significant differences in reporting across a large set of subgroups, reinforcing the finding that direct questioning techniques are quite accurate to monitor the evolution of IPV prevalence rates. However, differences by education are present even after multiple-hypothesis testing is accounted for: college-educated women underreport physical and sexual violence, while there is no bias among the less educated. This highlights the possibility of context-specific heterogenous effects that should be further explored to avoid misdiagnosis and targeting issues.
